ABSTRACT

Objective: Thyroid nodules, a clinical disease with high incidence, include benign and malignant types. This study aims to evaluate the diagnostic value of ultrasound-guided fine-needle aspiration cytology (US-FNAC) in determining the pathological nature of thyroid nodules and to conduct an in-depth analysis of its diagnostic efficacy across nodules of varying sizes.

Material and Methods: This retrospective study identified 116 patients undergoing thyroidectomy in Zibo Central hospital from January 2022 to March 2023, with 98 meeting the study's inclusion criteria. All patients received ultrasound and US-FNAC examinations before surgery to analyze the ultrasonic features of thyroid nodules. The diagnosis results of pathological natures obtained by US-FNAC were analyzed with the result of post-operative pathological examination as the gold standard. The patients were divided into four groups according to the median and quartile of nodular diameters to explore the diagnostic efficacy of US-FNAC for the pathological natures of thyroid nodules with various diameters and comprehensively evaluate its application value. The evaluation tool of diagnostic efficacy was the receiver operator characteristic (ROC) curve.

Results: A total of 98 puncture nodules were evaluated, with a diameter of 0.8–5.2 cm. Post-operative pathological examination showed 10 (10.20%) benign and 88 (89.80%) malignant lesions. The ultrasound examination showed 14 (14.29%) benign and 84 (85.71%) suspected malignant lesions. The US-FNAC results showed 2 cases (2.04%) of type I, 9 cases (9.18%) of type II, 3 cases (3.06%) of type III, 29 cases (29.59%) of type IV, 39 cases (39.80%) of type V, and 16 cases (16.33%) of type VI, including 9 (9.18%) benign and 84 (85.72%) malignant lesions and 5 (5.10%) uncertain pathological natures. According to the median and quartile of nodular diameters, specifically, Q1 (n = 24, ≤1.6 cm), Q2 (n = 26, 1.7–1.9 cm), Q3 (n = 24, 2.0–2.3 cm), and Q4 (n = 19, >2.3 cm). The results of ROC analysis showed that the area under the curve (AUC), sensitivity, and specificity of US-FNAC diagnosis were 0.894, 98.80%, and 80.00%, respectively. The AUCs of US-FNAC in groups Q1, Q2, Q3, and Q4 were 0.978, 1.000, 0.977, and 0.971. The AUCs of Q1 group, Q2 group, Q3 group and Q4 group were all > 0.9, and US-FNAC had high diagnostic efficiency for the pathological properties of thyroid nodules with different diameters.

Conclusion: US-FNAC has a high diagnostic efficiency for the pathological properties of thyroid nodules. Whether the nodule diameter has an effect on the accuracy of this method requires more clinical evidence.

INTRODUCTION

Thyroid nodules are a commonly observed condition in clinical practice with a complex etiology and can be classified as benign or malignant.[1] Related research results show that the incidence

of malignant nodules in patients with thyroid nodules is approximately 5.6–79.8%.^[2] Compared with patients with benign nodules, patients with malignant thyroid nodules have more serious conditions, and their physical and mental health and quality of life are affected,^[3–6] so timely identification of the pathological natures of thyroid nodules is vital.

The puncture technique was first used in the pathological examination of tumors in 1930 and was adopted in the cutting biopsy of thyroid diseases in the 1950s and 1960s. However, traditional coarse needle biopsy can lead to complications or metastasis of tumor cells along the needle tract, limiting its clinical application.^[7–9] Fine-needle aspiration biopsy (FNAB) is a newer technique that offers minimal injury, reduced pain, and ease of operation. FNAB effectively mitigates the complications and metastasis risks associated with coarse needle biopsy, thus reducing the need for unnecessary surgeries. Consequently, it has gradually become the biopsy technique recommended by clinical guidelines.^[10–12] Hence, higher requirements are placed on the puncture path and site accuracy because of the limited tissue dose obtained by fine-needle aspiration.

With the continuous improvement of modern medical technology and ultrasound equipment, ultrasound technology has also been used in thyroid nodule examination, which shows an increasing trend in the detection rate of nodules.^[13–15] Ultrasound-guided fine-needle aspiration cytology (US-FNAC) is a minimally invasive technique that effectively diagnoses the nature of thyroid nodules. Unfortunately, clinical reports on the diagnostic value of US-FNAC in determining the nature of thyroid nodules are scarce, and the relationship between the diagnostic efficacy of US-FNAC and nodular diameter has not been established. In this study, the result of post-operative pathological examination was the gold standard for analyzing the value of US-FNAC in diagnosing benign and malignant thyroid nodules and exploring its application effect in nodules of different sizes. This study aims to provide an effective reference for improving the accuracy of clinical diagnosis of nodular natures, determining treatment options, and evaluating prognosis.

MATERIAL AND METHODS

Inclusion and exclusion criteria

Inclusion criteria

Adult patients with thyroid nodules diagnosed by ultrasound, those undergoing resection surgery of thyroid nodules for the first time, those with basic listening, speaking, reading, and writing abilities, and those with complete clinical data were included.

Exclusion criteria

Patients with infection or skin injury at the puncture site after US-FNAC, puncture failure, cognition or communication

disorders, incomplete clinical data, treatments such as sclerosing agent injection, drugs, radiofrequency ablation before enrollment, the history of radiotherapy and tumor surgery, distant metastasis of malignant tumors, severe diseases in heart, liver and kidney or other tumor types, and those in lactation period or gestation period were excluded.

Study methods

This retrospective study was approved by the medical ethics committee of Zibo Central Hospital (approval no.: 2024052). Considering the anonymity of data, patients informed consent was waived. The study was conducted in accordance with the Declaration of Helsinki.

A total of 116 patients underwent thyroidectomy in Zibo Central Hospital from January 2022 to March 2023, whose eligibility was evaluated according to the inclusion and exclusion criteria to determine the study subjects. Clinical data and information related to ultrasound imaging, diagnosis and treatment of cytopathology, and post-operative pathological examination were collected for each subject. The ultrasound features of patients with benign and malignant nodules were compared. Taking the result of post-operative histopathologic examination as the gold standard, the area under the curve (AUC) value was calculated via receiver operator characteristic (ROC) curve to determine the diagnostic value of US-FNAC for the pathological natures of thyroid nodules.

Finally, the patients were divided into groups Q1, Q2, Q3, and Q4 according to the median and quartile of nodular diameters to further evaluate US-FNAC's diagnostic efficacy for the pathological natures of thyroid nodules with different diameters.

Examination and evaluation methods

Surgical pathological examination and evaluation

During the resection of thyroid nodules, all patients underwent resection of lesion nodules under general anesthesia, and a rapid pathological examination of diseased thyroid tissues was carried out. The collected specimens were transferred to the pathology department for assessment by two experienced pathologists at the level of attending physician or above. Consultation was necessary to obtain a unified diagnostic result if different opinions existed.

Typical cancer cells in the specimens were assessed as malignant, and non-typical cancer cells were assessed as benign.

Ultrasound examination and evaluation

The color ultrasound diagnosis equipment (model: Philips EPQ5) with L12–5 probe was selected for ultrasound

examination, and the probe frequency was 5–12 MHz. The patient was guided to adopt a supine position, and the pillow was placed behind the patient’s neck to tilt the head backward. After fully exposing the neck skin, ultrasound detected the bilateral thyroid lobes and isthmus and observed nodular location, size, number, morphological characteristics, blood flow, internal echo, and calcification situations.

According to the American Thyroid Association (ATA) guidelines, the ultrasound examination results could be divided into five types.^[16]

Benign

Simple cystic nodules (no solid component).

Super-low suspected malignancy

Spongiform or partially cystic nodules without any of the ultrasound features described in low, moderate, or high suspected pattern.

Low suspected malignancy

Solid nodules with equal or high echo or partially cystic nodules with eccentric solidity.

Moderate suspected malignancy

Solid nodules with low echo and smooth margins.

High suspected malignancy

Solid nodules (components) with a low echo of a partially cystic nodule with one or more of the characteristics including irregular edges (infiltrative, microlobulated), microcalcification, longer than wide shape, edge calcification combined with small prominent soft tissue component, and the evidence of extrathyroid extension.

US-FNAC examination and evaluation

According to the results of clinical and ultrasound examinations, the most suspected thyroid nodule was examined through US-FNAC. After disinfection and towel treatment, 2% lidocaine (NMPA approval no.: H37022114; specification: 5 mL: 0.1 g, manufacturer: Shandong Hualu Pharmaceutical Co., Ltd.; origin: Liaocheng, China) at a dose of 50–300 mg was used for local infiltration anesthesia. A 22 G fine needle was selected to puncture the corresponding suspected nodules under ultrasound guidance [Figure 1]. The multi-directional puncture should reach the nodular internals to obtain contents as much as

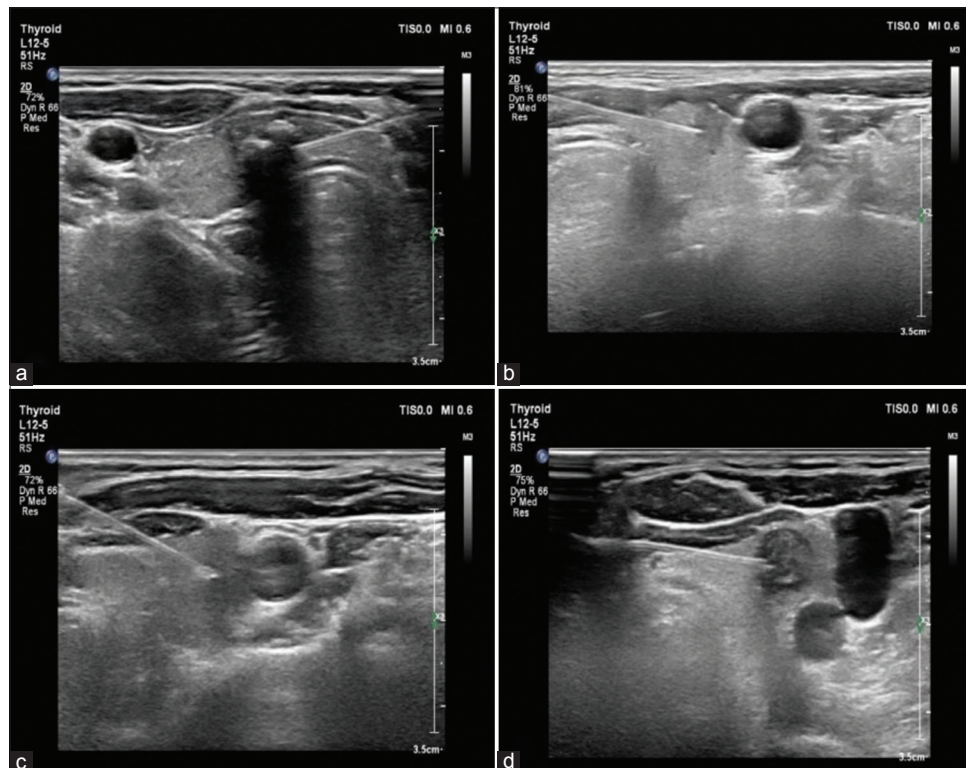

Figure 1: Ultrasound-guided puncture images in ultrasound-guided fine-needle aspiration cytology. (a) A low-echo nodule puncture was observed in the right lobe of the thyroid, and (b-d) was displayed in the left lobe of the thyroid.

possible. Negative pressure suction was reasonably adopted if the tissue was difficult to extract. If the aspirate contained more blood, the remaining blood was aspirated completely from various directions using a syringe after slightly shaking the glass slide, and then, the suction operations were performed three times, subsequently obtaining specimens. The syringe was withdrawn, the needlepoint was pressed with gauze, and the specimens were placed in the slide, and the slide method was used for examination. Two experienced pathologists (attending physician or above) evaluated the results. When there were different opinions, consultation was needed, and the final diagnosis results were obtained after the unification of opinions.

According to US-FNAC results, patients could be divided into the following six types.^[17]

1. Patients with non-diagnostic or unsatisfactory specimen results were classified as type I
2. Patients with benign lesions were classified as type II
3. Patients showing atypical cellular lesions with unclear diagnostic significance were classified as type III
4. Patients with suspected or existing follicular tumors belonged to type IV
5. Patients with suspected malignant tumors were classified as type V
6. Patients with definitely diagnosed malignant tumors were classified as type VI.

Statistical analysis

The pre-operative US-FNAC and post-operative paraffin pathology results of all patients with thyroid nodules were entered into the SPSS database (version: 26.0, developer: IBM Corporation; Armonk, State of New York, USA). The categorical variables were expressed as (*n* [%]) and tested by Fisher’s exact probability or the correction formula of the chi-square test, and continuous variables were tested by the Shapiro–Wilk test and the data meeting non-normal distribution were expressed as *M* (*P*₂₅, *P*₇₅). ROC curves were used to evaluate the diagnostic efficacy of US-FNAC. When *AUC* > 0.5, the *AUC* closer to 1 indicates a better diagnostic effect (i.e., *AUC* = 0.5–0.7 indicates low accuracy, *AUC*=0.7–0.9 indicates a certain accuracy, and *AUC* > 0.9 indicates high accuracy). Microsoft Office Word 2006 (Microsoft Corporation; Redmond, WA, USA) and SPSS software were used to create figures.

RESULTS

Baseline data

This study selected a cohort of 116 patients, of which 98 met the inclusion criteria [Figure 2]. Of these, 53 were female (54.08%) and 45 were male (45.92%), with an average age of 53.46 ± 6.62 years (ranging from 32–76 years).

Ultrasound classification	Number (<i>n</i> [%])
Benign	14 (14.29)
Super-low suspected malignancy	16 (16.33)
Low suspected malignancy	28 (28.57)
Moderate suspected malignancy	11 (11.22)
High suspected malignancy	29 (29.59)

Results of surgical pathological examination

In this study, 98 nodules were punctured, with a diameter of 0.8–5.2 cm and a median and quartile of (1.98 ± 0.70) cm, including 10 (10.20%) benign nodules and 88 (89.80%) malignant nodules, as shown in Table 1.

Ultrasonic classification and features

According to ATA guidelines, 98 thyroid nodules were classified, including 14 (14.29%) benign nodules and 84 (85.71%) suspected malignant nodules. The specific ultrasound classification results are shown in Table 2. The

Figure 3: Cytopathology in patients with thyroid nodules by ultrasound-guided fine-needle aspiration cytology. (a) Hashimoto's thyroiditis. Lymphadenia, formation of lymphoid follicles, and acidophilic degeneration of follicular epithelium among thyroid follicles were observed (100 µm). (b) Atypical follicular adenoma. Rich neoplastic cells, inconspicuous follicular structure in some areas, and mild heterogenic cells were observed (100 µm). (c) Oncocytoma. The eosinophilic infiltration of thyroid cells, consistent nuclear size, obscure heteromorphism, and complete fibrous capsule around thyroid follicles were observed, and no capsule and vascular invasion were observed (100 µm). (d) Subacute thyroiditis. Destroyed thyroid follicles and overflowed colloids, the infiltration of fibroblast hyperplasia, lymphocytes, plasma cells, neutrophils, and eosinophils, and the reaction of histiocytes and multinucleated giant cells were observed (200 µm). (e) Papillary thyroid carcinoma. Papillary structure and gravel-like calcification could be found (100 µm). (f) Medullary thyroid carcinoma. The cells were arranged in follicular, nested, and trabecular ways. The cytoplasm was bicolorophilic, the nucleus was round or oval, and the chromatin was coarse (200 µm). (3a-f: Hematoxylin and eosin)

composition, echo, calcification, edge, and shape of benign thyroid nodules were significantly different from those of malignant thyroid nodules ($P < 0.05$), and the specific ultrasonic features are shown in Table 3.

US-FNAC RESULTS

The US-FNAC results of 98 thyroid nodules showed 9 (9.18%) benign nodules, 84 (85.72%) malignant nodules, and 5 (5.10%) uncertain pathological natures, as shown in Table 4 and Figure 3.

Diagnostic efficacy of US-FNAC for the pathological natures of thyroid nodules

Because the benign and malignant natures of nodules in type I and type III could not be determined, 93 cases were included after excluding nodules in type I and III. The result of the post-operative pathological examination was used as the gold standard for ROC analysis, showing that the AUC, sensitivity, specificity, and 95% confidence interval of US-FNAC were 0.894, 98.80%, 80.00%, and 0.745–1.000, respectively, as shown in Table 5 and Figure 4.

Diagnostic efficacy of US-FNAC for pathological natures of thyroid nodules with different diameters

According to the median and quartile of nodular diameters, i.e., 1.90 (1.60, 2.30) cm, 93 patients were divided into groups Q1 (≤ 1.6 cm), Q2 (1.7–1.9 cm), Q3 (2.0–2.3 cm),

Classifications	Pathological natures	Total
Type I	Uncertain	2 (2.04)
Type II	Benign	9 (9.18)
Type III	Uncertain	3 (3.06)
Type IV	Malignant	29 (29.59)
Type V	Malignant	39 (39.80)
Type VI	Malignant	16 (16.33)

US-FNAC: Ultrasound-guided fine-needle aspiration cytology, Type I-VI:
 1. Patients with non-diagnostic or unsatisfactory specimen results were classified as type I.
 2. Patients with benign lesions were classified as type II.
 3. Patients showing atypical cellular lesions with unclear diagnostic significance were classified as type III.
 4. Patients with suspected or existing follicular tumors belonged to type IV.
 5. Patients with suspected malignant tumors were classified as type V.
 6. Patients with definitely diagnosed malignant tumors were classified as type VI.

and Q4 (>2.3 cm). The results of ROC analysis showed that the AUCs of US-FNAC in the above groups were 0.978, 1.000, 0.977, 0.971. The AUCs of Q1 group, Q2 group, Q3 group and Q4 group were all > 0.9, and US-FNAC had high diagnostic efficiency for the pathological properties of thyroid nodules with different diameters, as shown in

Table 6 and Figure 5.

DISCUSSION

Fine-needle aspiration cytology and ultrasonic examination are key tools for pre-operative evaluation of patients with thyroid lesions.^[18-20] Ultrasound examination provides a reference for nodular selection in US-FNAC. Ultrasound guidance assists physicians in seeking a more accurate puncture path and the best puncture position, thus effectively avoiding blood vessels and nerves and improving the success rate of puncture while ensuring safety. In comparison with palpation-guided fine-needle aspiration cytology, US-FNAC has higher accuracy.^[21] A foreign study indicated that ultrasound features such as low echo, fine calcification, irregular edge, and nodular aspect ratio >1 were potential indicators of malignant thyroid nodules.^[22] This is consistent with the result of the analysis of this study, which fully confirms the application value of ultrasonic examination in fine-needle aspiration cytology of thyroid nodules.

The US-FNAC results in this study showed 9 (9.18%) benign nodules, 84 (85.72%) malignant nodules, and 5 (5.10%) nodules with uncertain pathological natures 2 (2.04%) specimens had unsatisfactory diagnoses, and 3 (3.06%) specimens were atypical cellular lesions with unclear diagnostic significance). According to surgical pathology results, two benign nodules

and one malignant nodule were not correctly diagnosed in this study, including that two nodules were diagnosed as Hashimoto’s thyroiditis by pre-operative US-FNAC but were diagnosed as papillary carcinoma by surgery. Hou *et al.*^[23] have also obtained similar results, finding that Hashimoto’s thyroiditis, a risk factor for the increase of false-negative rate, would reduce the diagnostic accuracy of US-FNAC. There may be two main reasons for this phenomenon, uniform lesions can result in omission during the puncture process, and second, insufficient experience among physicians can lead to incorrect cytopathologic diagnoses. In addition, one nodule was diagnosed with a malignant tumor by pre-operative US-FNAC but was diagnosed as Hashimoto’s thyroiditis by surgical pathology, speculating that it may be related to the limitations of US-FNAC. US-FNAC is based on ultrasonic features, but some benign nodules are easily misdiagnosed as malignant tumors because of irregular edges and uneven echoes.

It has been reported that the accuracy of US-FNAC may also be affected by the size of thyroid nodules.^[24,25] In response to this problem, this study divided the patients into four groups according to the median and quartile. Statistical analysis

found the AUCs of groups Q1, Q2, Q3, and Q4 > 0.9 , and US-FNAC had high diagnostic efficiency for the pathological properties of thyroid nodules with different diameters. We speculate that this may be related to the small number of cases in our study. The needle may slide out of the nodule during sampling or enter the normal tissue. In addition, Zhao *et al.*^[26] point out that nodular size has a certain effect on the positive rate of fine needle aspiration, mainly due to the lower diagnostic efficiency of conventional ultrasound on suspected malignant features in small nodules. Therefore, it is necessary to actively perform long-term follow-up for patients with thyroid nodules in types I and III through US-FNAC and patients with small nodular diameters and perform repeat punctures if necessary.

However, US-FNAC diagnosis is also susceptible to factors such as clinical physicians’ diagnostic experience and proficiency.^[27-29] In this study, two patients were excluded due to inexperienced physicians who caused puncture failure, with an incidence of 1.90% (2/105) when screening patients, and this situation needs attention, although the incidence is not high. It is advocated that experienced physicians should perform

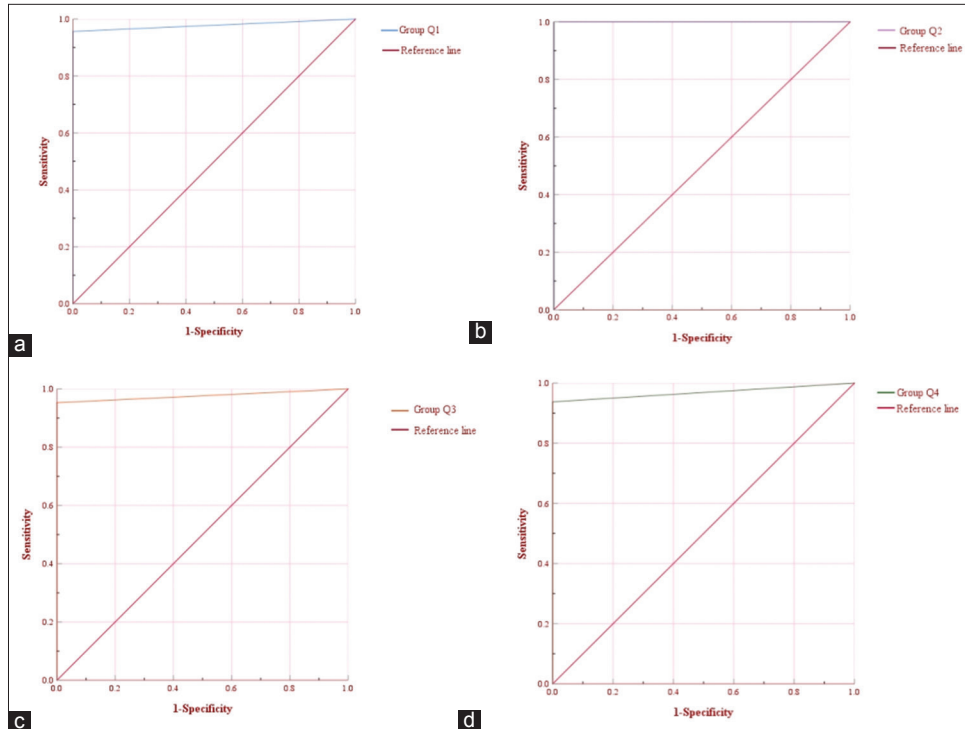

Figure 5: Receiver operator characteristic (ROC) curve of ultrasound-guided fine-needle aspiration cytology (US-FNAC) in diagnosing pathological natures of thyroid nodules with different diameters. (a-d) Shows the ROC curve of US-FNAC in the diagnosis of groups Q1, Q2, Q3, and Q4. 93 patients were divided into groups Q1 (≤ 1.6 cm), Q2 (1.7–1.9 cm), Q3 (2.0–2.3 cm), and Q4 (> 2.3 cm).

US-FNAC, and patients should experience comprehensive evaluation before puncture to minimize the occurrence of adverse conditions such as insufficient sample acquisition, diluted blood cells caused by bleeding at the puncture site, and failure of puncture to reach the lesion site, thereby improving the effectiveness, accuracy, and safety of US-FNAC.

There are some limitations in this study. First, among patients undergoing US-FNAC, most patients with malignant nodules and few patients with benign nodules will receive surgical treatment, so selection bias occurred. Second, this single-center study had small sample numbers, so subsequent studies need to extend the observation time and increase the samples. Finally, the different studies had multiple grouping criteria for nodular size, affecting the study results. Therefore, complete verification should be taken by including more samples and conducting multiple studies to provide more reliable information for clinical work.

SUMMARY

US-FNAC has a high diagnostic efficiency for the pathological properties of thyroid nodules. Whether the nodule diameter has an effect on the accuracy of this method requires more clinical evidence.

NextGen CelBloking™ Kits

**Frustrated with your cell blocks?
We have a better solution!**

Nano

Nano NextGen CelBloking™

Cell block kit to process single scattered cell specimens and tissue fragments of **any** cellularity.

PATENT PENDING

Pack #1

Pack #2

Micro

Micro NextGen CelBloking™

For cellular specimens (more than 1 ml concentrated specimen with Tissuecrit more than 50%)

PATENT PENDING

Pack #2
